ABSTRACT

The purpose of this thesis is to design and implement the input translator for the Computer System Design Environment, which is a computer-aided design system. The Computer System Design Environment is used to design real time controllers for a variety of purposes. The input translator will take an input, which has been developed in the prescribed language, CSDL, and with the aid of a partial syntax-directed editor, translate it into primitive list form. This form is used by the remainder of the system to select the best hardware and software components, as described in a set of realization libraries, to build the proposed controller.

I. INTRODUCTION AND BACKGROUND

A. COMPUTER-AIDED DESIGN

Computers, as design tools, are beginning to touch every facet of our lives. We can turn on our television sets to see an advertisement for an automobile with a computer being used to aerodynamically design the body style of the car. Architects are using computers to assist in modern drafting and architectural design techniques [Ref. 1]. The potential for automating the design of many other products exists and research in all areas of computer-aided design (CAD) is continuing at a prolific rate.

While research in the areas of artificial intelligence may lead us someday to a computer which can, using natural language understanding, solve problems reserved for only humans today, current technology limits us to those problems where the computer relies on human expert input for a knowledge base. A knowledge base developed by human experts is used by the computer to derive a design much faster than a human and reduce the concern over the complexity of the process. The computer can maintain a large data base of components from which it can pick to satisfy a criteria as described by the designer. While not really creative, this system allows the mixing and matching, automatically, of components to produce the best combination available. The advantages to be gained are a decrease in the time it takes to complete the design process and error free results, while leaving the human designer to concentrate on the desired specification.

One of the most important features of such a system is its accessibility. The user interface must be one that meets the needs of the designer while remaining within the bounds of current technology. The interface must be user-friendly to the greatest possible extent. It is this particular portion of the problem which has given rise to the most debate and brought forth the widest range of possible solutions.

B. COMPUTER SYSTEM DESIGN ENVIRONMENT

The Computer System Design Environment (CSDE), under development at the Naval Postgraduate School in Monterey California, is one such computer-aided design system. It is based on the research contained in LtCol. Alan Ross's doctoral dissertation [Ref. 2]. Ross's work is an expansion and realization of the research conducted by M. N. Matelan [Ref. 3]. The first CSDE implementation is one in which real-time controllers (microprocessors) are designed based on a realization library (knowledge base) of current microprocessor technology. The system creates the problem statement in a syntax-directed editor, translates it into an intermediate form, selects a microprocessor realization from the library and generates the software and hardware component descriptions to implement the design. The components are used to select a processor volume or implementation. The volume checked to see if the timing constraints, set forth by the designer, can be achieved. If so, the monitor is generated and the output is formatted. The monitor produces the software and ancillary hardware to realize the correct strategy. If the timing constraints cannot be met, a new volume must be chosen and tested. The CSDE gives a designer the tools to derive the appropriate components that make up the controller, no matter what its task is to be.

Motivation and discussion of the CSDE are contained in [Refs. 2 , 3].

C. PREVIOUS WORK

The modules that make up the Computer System Design Environment are depicted in figure 1.1. Matelan described a Control System Design Language (CSDL) as the input language for this system [Ref. 3]. Using CSDL with a syntax-directed editor keeps the input details at a high-level of abstraction while completely describing the proposed design.

To fulfill the input requirements of block 1 in figure 1.1, a syntax-directed editor was designed and partially implemented as a result of Lt. Barbara Sherlock's thesis at the Naval Postgraduate School in 1983 [Ref. 4]. Lt. Sherlock's editor receives a high level input description of the problem from the designer, formats it and passes it to the input translator. This form is a combination of Matelin's CSDL and ADA, the Department of Defense sponsored design language. This language, as the basis for input to and output from the editor, follows the concept that the problem statement should not require the designer to be proficient in the details of a high level programming language. The translator, as its name suggests, translates the output from the editor into an intermediate form acceptable to the follow on CSDE processes. Its design and implementation are the subjects of this thesis. The optimizer and functional mapper (Blocks 3 and 4, Figure 1.1) exist as Fortran programs in the CSDE. The optimizer requires an 80 column format for its input which is a primitive list or the set of functions that the controller will perform, in an almost assembly-like language format. It is developed from the contingency and procedures sections of the design input statement. Hardware availability

Figure 1.1 Computer System Design Environment.

prescribed this format when the CSDE was originally implemented by LtCol. Ross. Work is currently in progress to install both the design input and the realization library in a relational database, thereby updating the optimizing and mapping processes [Ref. 5]. But the basis of the input to these sections of the system, which is the primitive list, will remain the same.

D. SCOPE OF THIS THESIS

The purpose of this thesis is to design and implement the input translator for the Computer System Design Environment. The translator must take the problem statement, a design for a real time microprocessor controller, and translate it into a list of primitives and a symbol table which can then be mapped across a realization library to determine the most feasible components. Appendix A is an example of a problem statement in the Computer System Design Language developed by Matelan. In addition, the translator must produce a timing table which can be used by the timing analyser to determine a feasible monitor to control the complete device [Ref. 2]. The timing table is developed using the contingency section of the problem statement which contains the timing requirements for the problem.

The next chapter of this thesis describes the design considerations for the translator and provides the detailed discussion of its requirements. The following chapters discuss the implementation and testing of the translator and the conclusions reached during the work. In addition, Appendice D includes the code for the translator with appropriate documentation.

II. TRANSLATOR DESIGN

A. DESIGN REQUIREMENTS AND CONSTRAINTS

As previously discussed, the input translator can be thought of as one of several modules in the CSDE system. In the CSDE hierarchy, it lies between the designer and the optimizer. If we consider, for a moment, the module as a black box, then we can better describe its function. The input to the module is a specification, written by the designer, for a real time controller. While Lt. Sherlock, in her design of the input editor [Ref. 4], decided to produce a pseudo-ADA specification language as the output of the editor, the translator being designed by this author will use the Control System Design Language. If the ADA output was to be adapted, this language would have to be formalized and a grammar produced that is capable of being parsed. In addition, the pseudo-ADA provides no real advantage, as the specification must be parsed and the same output produced no matter what the language. Therefore, with the additional knowledge that the editor is the subject of a current thesis project which will return to the CSDL output, the decision was made to write the translator for that CSDL. A partial example of the CSDL description is contained in figure 2.1.

The output from the translator consists of a primitive list, a symbol table, and an application timing table. The primitive list is intermediate code which reflects the requirements of the input while the symbol table contains all input variables and their attributes. The application timing table contains the contingencies with their related tasks and all supplied timing values from the problem definition. This table is used during the timing analysis.

  IF BUFFER /= OLDBUF THEN DATA_READY := 1 END IF;  
EXIT DATA_READY;
```

Figure 2.1 A Partial Example of CSDL.

The requirements, then, exist for the input language, CSDL, to be analyzed to determine what method of translation is to be employed. In addition, the required output must be standardized among the system modules so the proper semantics can be developed for the translation process. Each of these issues will be discussed in detail in the following sections.

B. CSDL- THE INPUT LANGUAGE

A translator accepts a source program, written in a source language, and transforms it into an object program [Ref. 6]. A source language designed for use in a computer aided design system and utilized in CSDE is the Control System Design Language (CSDL), the origin of which was previously discussed. It is composed of an alphabet whose individual elements are called tokens and a grammar which expresses the rules governing the legal classes of token strings. The tokens can be further subdivided into terminals

and nonterminals. Terminals are the letters of the allowed alphabet while the nonterminals are representations of strings in the language which increase the expressive power. A partial example of the production rules for CSDL is contained in figure 2.2. The syntax for CSDL, which includes the alphabet and grammar, is contained in Appendix B.

```
<WHEN DO> ::= <QUALIFICATION> WHEN <NAME>
              <EPISODE TIMING> DO <TASK LIST>

<TASK LIST> ::= <NAME> / <TASK LIST> THEN <NAME>

<NAME> ::= *ID* / *ID* ( <EXPR LIST> ) /
            *ID* *NUMBER* : *NUMBER*
```

Figure 2.2 An Example of CSDL Syntax.

Different types of translating devices accept different languages classifications. To narrow the choice of translator designs, it must be determined which classification fits CSDL. Neither Matelan nor Ross, in their early work on CSDE, included this description [Refs. 2 , 3]. So, a brief review of language classification will assist in this determination. Chomsky distinguished four general classes of grammars [Ref. 7]. Without turning this section into a text on language theory, these are, from the most general to the most specific: unrestricted, context-sensitive, context-free, and right-linear. Context-sensitive and context-free are subsets of the unrestricted class, while the right-linear and two other grammars related to the right-linear

grammars, left-linear and regular, are all subsets of the context-free grammars. These classes allow us to define sentence recognizing machines which form the basis for translators. CSDL falls into the category of context-free grammars. This is the set which, in its production rules, has any string of terminals and nonterminals on the right-hand side of the production while the left-hand side is restricted to nonterminals only. The classes of right-linear, left-linear, and regular grammars restrict the order and appearances of terminals and nonterminals on each side of the production rules and CSDL does not fall into one of these categories. Context-sensitive grammars allow terminals as well as one nonterminal on the left-hand side of the production rules and, while CSDL does fit this category, the context-sensitive are a super-set of the context-free grammars, so this is not an issue when we try to develop the machines which can recognize CSDL.

Each of the phrase-structured grammar classes has an automaton associated with it. The right-linear grammars can be recognized and accepted by a finite-state automaton which consists of a finite set of states and a set of transitions between pairs of states. Each transition is associated with some terminal symbol. The context-sensitive grammars are recognized and accepted by a two-way, linear bounded automaton which is essentially a Turing machine whose tape cannot grow longer than the input string. And, finally, context-free grammars are recognized and accepted by a finite-state automaton controlling a push-down stack, with rules governing the operations on the stack [Ref. 6].

Matelan states that CSDL was created as a context-free grammar and inspection of the syntax contained in Appendix B confirms this [Ref. 3]. In order to recognize strings in the language and translate them into the prescribed primitive-list format a finite-state automaton with a push-down stack will be developed.

C. PARSER ALTERNATIVES

It was shown above that CSDL is a context-free grammar and a push-down automata will be required as the recognizer for strings in the language. Additional properties of CSDL must be investigated to further define the problem of parsing. In a context-free grammar each nonterminal can be expanded into some terminal string independently of its neighbors, and its expanded string essentially "pushes aside" its neighbors without interfering with their order in any way [Ref. 6]. But we do impose some ordering rule for the selection of the next nonterminal to replace, in a sentential form for a canonical derivation. The most common rules are left-most and right-most. In a left-most derivation, the left-most nonterminal in each sentential form is selected for the next replacement and in a right-most, the right-most nonterminal is selected. Most common programming languages are easily parsed from left to right, but with difficulty from right to left. Furthermore, algebraic operations are usually performed from left to right, by convention, so it is the order that will be considered. A top-down parse of some sentence, scanning from left-to-right through the string, corresponds to a left-most derivation while a bottom-up parse works from a given sentence upward toward the start symbol, in a left-to-right manner. [Ref. 6].

There are some rules governing the use of these two types of parsers which affect the choice of one for use in recognizing CSDL. Top-down recognition with a look-ahead of k symbols is only possible on a subset of the context-free grammars called $LL(k)$ grammars. Although it is not obvious whether a grammar is $LL(k)$, there is one property which is relevant in this discussion. An $LL(k)$ grammar has no left recursive nonterminals, i.e., a nonterminal A , such that $A \Rightarrow$

Aw for some w, a string in the language [Ref. 6]. It can be quickly determined by examining Production 17 in Appendix B that CSDL is left-recursive. In fact, it is full of recursion. There are algorithms for removing left-recursion in grammars and for a small grammar that would be the choice. But CSDL has 190 production rules and removing the extensive recursion would increase the grammar size an unacceptable amount. So top-down parsing will be discarded as a possible parsing method.

A bottom-up LR(k) parser is the other major type of recognizer under consideration. A grammar is said to be LR(k) if, for every derivation, the production $A \Rightarrow x$ can be inferred by scanning ux and at most the first k symbols of v in the following derivation step: $uAv \Rightarrow uxv$. The major advantage of this method is that an LR(k) parser can be constructed for any context-free grammar. This would eliminate the necessity to remove the left-recursion from CSDL.

There is one other major advantage in choosing a bottom-up LR(1) parser automaton. An automatic parser generator can construct, using a computer, the language specific tables that control the operation of the automaton. The LR package from Lawrence Livermore Laboratory [Refs. 8, 9] is such a system which constructs the tables. Having it available on the Vax 11/780 at the Naval Postgraduate School made the decision easy. It, also, has the advantages that the parsing routine is guaranteed to be correct, the CSDL grammar can be changed easily when necessary, and the resulting translator becomes simple and efficient. For the details as to how the package works see References 7 and 8.

D. PARSER STRUCTURE

The structure of the parser will follow the technique described by G.J. Myers in his book, Composite Structured Design [Ref. 10], and utilized in the design and implementation of an ADA pseudo-machine by Captain Alan Garlington in his thesis [Ref. 11]. The hierarchy for such a technique is

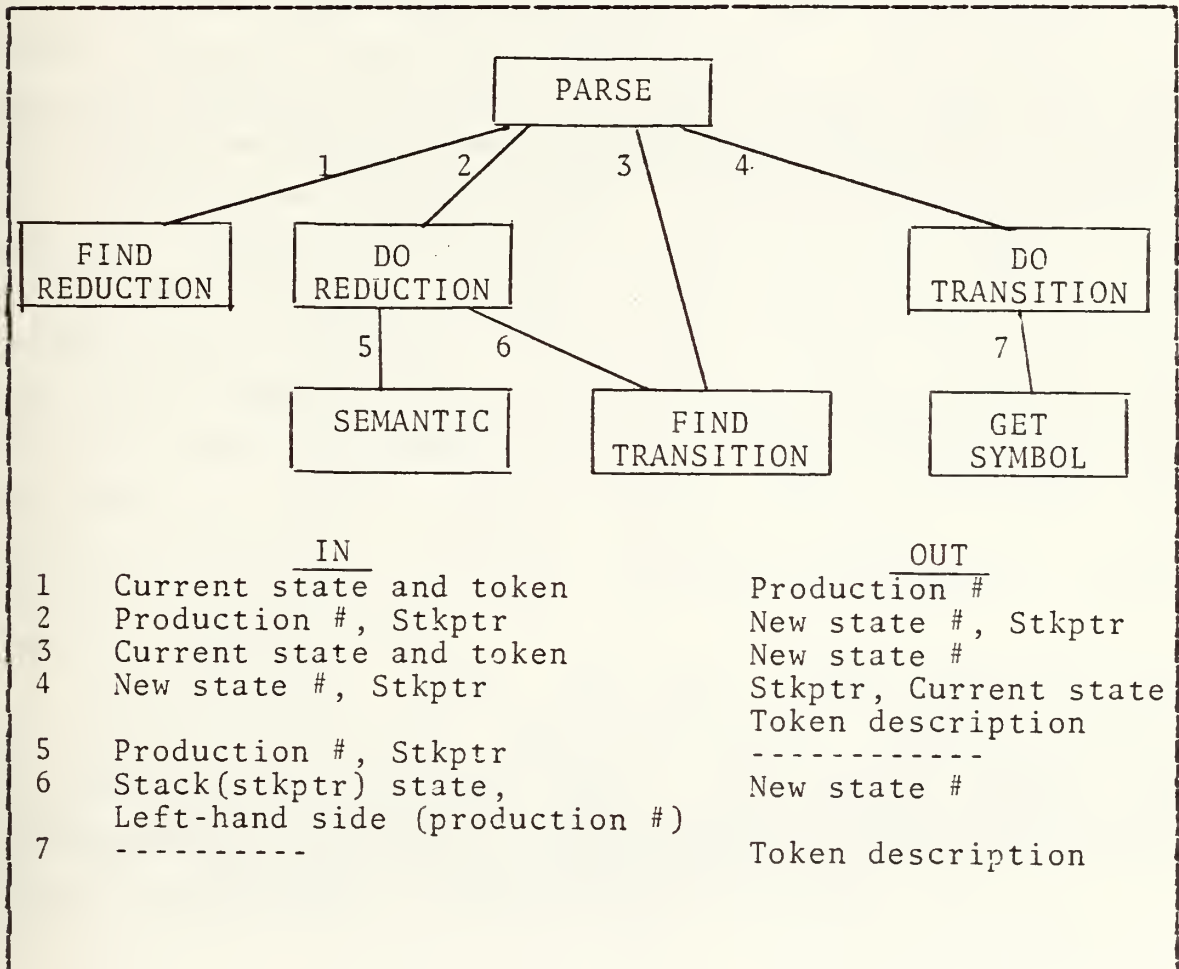

Figure 2.3 Parser Structure.

depicted in figure 2.3. The top module, PARSE, provides FINDREDUCTION with the current state and current look-ahead symbol. FINDREDUCTION returns a production number if any

reduction exists. PARSE then calls DOREDUCTION and the sequence is repeated. If no reduction exists, PARSE calls FINDTRANSITION to see if any transitions exist. DOTRANSITION accomplishes the transition and the routine repeats until a final state is reached. If no transition exists, an error is detected and the routine either attempts to recover or halts depending on the severity of the error.

The parser maintains two stacks, one to store the next token and one to store the current state. When DOREDUCTION provides SEMANTIC with the production number, the components of the production have been placed on the stack and SEMANTIC can take the proper action. This action could include adding a symbol to the symbol table with its appropriate parameters, calling an error routine, or nothing. After completing the semantic actions the items on the stack are removed by DOREDUCTION and the proper token replaces them. Various auxiliary procedures and error routines will be necessary to complete the translator. These procedures will include the input and output routines required to read the designers input and place the created primitives and symbol table in proper format.

The translator, thus, will take a CSDL description of the desired controller, check for errors, parse the input, and produce the primitive list, the symbol table, and application timing table. The implementation of the translator is discussed in the following chapter.

III. TRANSLATOR IMPLEMENTATION

A. LANGUAGE OF IMPLEMENTATION

The Computer System Design Environment was originally implemented in Fortran, with the system maintaining its data base on formatted punch cards for use in a batch environment. Feasible alternatives exist and have been investigated in subsequent research. CSDE is now installed in the Vax 11/780 at the Naval Postgraduate School, with interactive computing available in a variety of programming languages. However, it is still maintained, mainly, in Fortran. It has been shown to be conceptually feasible to represent the data base requirements of the CSDE by a relational model [Ref. 5]. Future intentions are to realize this concept on a data base management system such as Oracle, which is available on the Vax machine. The importance of this is that format, such as column numbers and location of data, and interface compatibility lose their importance and the relations between the data and the representations of the relations become major concerns.

An additional property required for the implementation language is maintainability. CSDL will not be static, as previously discussed. As hardware technology changes, the realization library will have to be updated and, accordingly, CSDL will have to be modified. This will result in an update to the translator, reflecting, possibly, such changes as new primitives. A high level familiar programming language will ease the burden of maintenance for future users.

Pascal is a high level programming language which supports the above requirements and, therefore, was chosen over the possible alternatives. Pascal is familiar to most programmers and, in fact, is the "first language" taught to new Computer Science students at the Naval Postgraduate School. In addition, it is easily understood by programmers conversant with other block-structured languages.

The modularity available with Pascal's procedures, functions, and high level constructs will provide maintainability. Each major function in the parser will comprise a Pascal procedure, making the main body of the program simple. Also, a section to be modified or updated is self-contained, and can be separately compiled and debugged following changes.

Perhaps the most important reason for selecting Pascal is the expected improvements in the CSDE system data base. When the libraries are placed in a relational database, and the designer's input must be mapped to a library in such a system, the data structures comprising the translator's outputs will require change. Pascal data structures are powerful and adaptable to a relational model, enabling this major modification to be completed without difficulty. Until such time as this occurs, the output will be of the form dictated by current system implementation. The details of this will follow.

B. TRANSLATOR INPUT

The input to the translator is the designer's requirements for a controller, written in the Control System Design Language, an example of which is contained in Appendix A. At this writing, a partial syntax-directed editor is under development which will create, based on the designer's ideas, the input in syntactically correct form. No

conceptual basis for the storage or file format of the input has been previously discussed, so several assumptions were made to enable production of the translator. Since the program is to be written in Pascal and reside as a member of the larger system, the CSDE, a simple file containing the CSDL problem description, which is read by the translator, will be utilized as the method of input. The file will be a text file with the only formatting restrictions being those imposed by the syntax of CSDL, the language being parsed. While this method of input will, currently, require some hands on system manipulation during run time, it is envisioned that a system macro can easily be developed at a later date to automate the process.

It is intended that the input be provided to the translator in syntactically correct form. However, as mentioned above, the means for this is not yet implemented. As example problem statements and test cases have been generated to exercise the translator, a requirement has developed for syntax error detection. This requirement can be eliminated and the ensuing code removed upon completion of the editor.

C. PRINCIPAL PROCEDURES AND DATA STRUCTURES

The parser was summarized at a high level of abstraction in Chapter 2 of this thesis. This section will point out the important procedures and data structures employed by the translator. The supporting functions which complete the translator are described as they appear in the program in Appendix D.

The tables produced by the automatic parser generator, which control the operation of the parser, are placed in arrays. The array sizes were set in program constants and would be modified if a change to CSDL caused a modification

to the tables. In addition, the symbol table, the state and lookahead stacks, and the temporary and constant lists are all implemented as arrays of records. Each record contains such information as the type and precision of the variable or constant and a pointer to the next record in the list. With the continuous manipulation of these data structures, such as pops and pushes on the stacks as well as the requirement for access to each member of each list, it was determined that this implementation allowed the maximum degree of flexibility. Also, the size of each data structure was described by a program constant, in order to improve maintenance. A limit might change in a situation where a controller design required a large number of input and output signals or internal variables, exceeding the maximum allowed for a stack.

Four sections conceptually comprise the translator program. The first is the initialization sequence, comprised of the procedure INITIALIZE and supporting functions. This section sets the initial values for all program variables and initializes the temporary and constant lists as well as the input symbol table to null values. It also establishes the SYMTABLE, which is a list containing all reserved words in CSDL, each located by a pointer. This table is used in the program to check each input token to determine whether it is a reserved word, identifier, or operator. Additionally, INITIALIZE includes the procedures for sending the generated primitive list, symbol table, and scratch pad to output files.

The next section is the actual parsing routine, comprised of the procedures PARSE, FINDREDUCTION, DOREDUCTION, FINDTRANSITION, DOTRANSITION, and their supporting procedures and functions. This sequence of code, essentially, repeats itself, looking at each input token, retrieved by GETSYM, and attempts to move through the

required production until a final state is reached. The tokens are placed on the stack and if a reduction can be performed, control moves to the semantic portion of the program. If one cannot be done, the sequence finds the transition and continues movement through the production rule, getting the next input symbol, with the stack unchanged. If no transitions exist, an error is present in the input.

When a reduction number, which corresponds to a production number in the CSDL grammar, is found, the program sequences to the third main section which contains the semantic operations for the program. It includes the procedures SEMANTIC and SEMANTIC1. These are two large case statements which, for each production, do the proper stack operations and send the output information to the procedures in the initialization section to be formatted and filed. The semantic operations are called from within DOREDUCTION, but really comprise a separate module within the structure of the translator.

The last section of the translator is the set of procedures comprising the error handling routines. This includes procedures PRINTERRORS, RECOVER, ERROR, and PRINTLINERRORS. The parsing routine attempts to recover, using the procedure of the same name, from an error while documenting it to the user. If the parser cannot recover, the program will halt and print the complete list, in a file, of the errors noted prior to the crash. This error handling sequence can be eliminated from the translator, as previously noted, on completion of a syntax directed editor, which would ensure error-free input.

D. TRANSLATOR OUTPUT

1. Primitive List

The primary output of the translator is the primitive list, a sample of which is contained in figure 3.1. This list of primitives is similar to a set of macros with

```
P 1s.generated for:DATAA
P 2s.proc      {DATAA:}
P 3s.sensecond {FLGA:1}
P 4s.eq        {@T01,FLGA,@C01:8,1,8)
P 5s.jmpf      {@T01,@01:8)}
P 6s.assign    {DATAA,@C01:1,8)
P 7s.loc       {@01:)}
P 8s.exitproc  {DATAA:)}
```

Figure 3.1 A Sample of the Primitive List.

the operands and attributes corresponding to parameters. It is converted by the Optimizer module, in the CSDE, to the internal format required by succeeding modules [Ref. 2].

In the initial implementation of CSDE there was no front end, i.e., the modules for the designer input and translation to intermediate form did not exist. Therefore, the information required in each primitive was hand generated and formatted by column number so it could be inputted in batch form as a card image file. Because the information is still required in the same format, the output, containing the primitive list and called PRIMFILE, was set up in an identical manner. Each primitive is one line and spaces were added to emulate the blank columns on a punch card. The name of the primitive appears first (software primitives preceded by s., hardware by h.). This is followed by the operand list and selection list (if any) separated by a colon [Ref. 16].

The primitive list, also, contains the design criteria, preceded by d., which allows the designer to specify the order of consideration of the realization volumes. The generation of many realizations can also be requested, each of which is presented along with its chip count and power requirements. The final portion of the primitive list is the application timing table, with each line preceded by a beginning A. This table includes the timing constraints and associated requirements. Further details concerning the information present in each column in the sections of the primitive list are contained in Reference 2 and, therefore, will not be discussed here.

The primitive names, such as eq and mult, were chosen to correspond as closely as possible to the operation suggested, but the names in the realization volumes must be identical to the ones emitted by the translator for the CSDE to function. They are easily modified in the semantic portion of the program if required. However, new operations will dictate a modification to the CSDL grammar with additional productions and semantic rules.

2. Symbol Table

The concept of a symbol table, for use by succeeding modules in the CSDE, is a result of this thesis. With the format required in the primitive list, it is difficult for the modules to look up, during the mapping, the attributes such as type, precision, value, and technology for controller variables and constants. It is thought that if this information were available in an easily read form, it would increase the speed of the realization process and raise the level of system efficiency. The functional mapper could read the symbol table first, and generate memory requirements for the controller prior to addressing the operations.

A symbol table can take as many forms as there are formats for a file. The data structure used to hold the information is also arbitrary. At the time of this writing, no decision has been made as to the ideal implementation. So, the information will be dumped into a file in the same format as the primitive list and can later be changed. This information includes all variables with their initial value and precision, all required memory locations, and all constants. In addition, the input and output ports with the expected signal names, technology, and precision are included for possible use. The code to format the symbol table can either be written in a separate small routine to be installed as a system module, or could be added to the translator. Whichever the case, a decision in this matter may well come in time for the code to be included in the final version of the translator for this thesis, in which case it will be reflected in the example symbol table in the appendices.

3. Scratch Pad

A scratch pad file developed naturally as the translator was designed and implemented. Used initially for output, it significantly aided the debugging and verifying of the processes. Error routines, mentioned previously, send error diagnostics to this file. Traces of parser execution which were developed out of necessity as part of the debugging process also needed an output medium. Because of this, the scratch pad became a formal part of the translator. This file, TRANSLATE, is a text file, with no particular format, containing information which can be helpful to the user. If an error is detected in the input, the diagnostic, which traces the error, will appear here, with comments as to possible corrective action.

In addition, three toggles have been included which provide, if desired, 3 types of traces of program execution. TRACEPARSE will trace the parsing action, providing the transition and reduction numbers as the parser moves through the input. TRACETOK provides the input tokens, one at a time, as they are read. PRINTTABLE displays the controller symbol names with their attributes. These toggles are activated by including "--#" followed by a toggle name at the head of the input file. More than one toggle per execution can be utilized, but the ensuing report becomes difficult to comprehend.

IV. TESTING AND VALIDATION

A. THEORY OF TESTING

The theory of software testing is a difficult problem and the subject of extensive research. Preliminary reports from this research indicate varying effectiveness. Dijkstra says that debugging can only show the presence of errors, but never their absence [Ref. 12]. It is commonly agreed that program testing cannot assure program "correctness" except under special circumstances. But the debate over Dijkstra's statement continues because others have developed theorems which challenge his reasoning [Ref. 13].

The most important factor in testing is to have a well-understood goal for the testing process. In the case of the input translator, proving correctness was not at issue. The algorithm for the parser is well proven to be a correct one [Ref. 9], so the detection of bugs in the program was the goal. Methods of testing include top-down versus bottom-up, static versus dynamic, white box versus black box, and other less known systematic approaches. In bottom-up testing, the idea is to build the program with proven (bug free) components, while top-down begins with tests of the highest level using stubs to simulate the activity of the lower level modules. Static testing attempts to demonstrate the truth of an allegation, i.e., it roughly corresponds to bench-testing a power-driven device without applying power, and dynamic testing seeks to exercise a program in a controlled and systematic way. The white box testing approach is, knowing any part of the software system is present for some specific reason, then relating each piece of a software system to the requirement it fulfills. The black box method

is an extensive testing approach which attempts to demonstrate the presence of function by concentrating on the exterior specifications of the software system [Ref. 14].

Just these brief examples illustrate the fact that software testing is not a well-defined science. The primary reason for this is that the concern for software reliability is relatively new. Only in the past decade has any notable effort been expended in understanding how a program can be proven correct or demonstrated to be reliable.

In selecting possible approaches to establish the reliability of the input translator, a combination of methods was determined to be the best. As previously noted, program correctness is not the objective. Also, the individual modules were completely debugged as they were built. So the problem reduces to ensuring the function between the input and output is such that the correct output is realized for each possible input. This is a black box methodology, but, since the program is to be exercised as a whole, the concept of dynamic testing also applies. The following section discusses the results of this testing and validation.

B. TEST RESULTS

Functional testing, a form of dynamic testing, involves the testing of a system over each of the different possible classes of input, the testing of each function implemented by the system, and the generation of test output in each of the possible output classes [Ref. 15]. This is the methodology that was employed in the testing of the input translator.

The CSDL input is divided into 5 parts which are IDENTIFICATION, DESIGN CRITERIA, ENVIRONMENT, PROCEDURES, and CONTINGENCIES. Each of these sections was examined in detail to determine the finite set of permutations in structure and content, as set forth by the CSDL grammar.

These possibilities formed the basis for test cases to be used in exercising the input translator. Due to its complexity, the PROCEDURES section received the most attention, but each part is discussed, in terms of the test results, below.

The IDENTIFICATION section, an example of which is contained in figure 4.1, consists of 3 character strings

```
IDENTIFICATION
DESIGNER: "Thomas H. Carson"
DATE: "10 April 1984"
PROJECT: "Start Malfunction Controller"
```

Figure 4.1 IDENTIFICATION Section of the Input.

which make up a portion of the documentation for the system. The strings are not parsed by the input translator, just simply read and ignored. This section is optional, as are they all, and the parser performs no other action on it.

The DESIGN CRITERIA, an example of which is contained in figure 4.2, allows the the user to specify the metric and number of monitors and volumes to be employed in the mapping process, the next module in the CSDE system. The metric is one of 3 choices, all character strings, while the monitors

```
DESIGN CRITERIA
METRIC FIRST;
VOLUMES 1;
MONITORS 1;
```

Figure 4.2 DESIGN CRITERIA Section of the Input.

and volumes are integer values. The parser reads each of these and checks for correctness in terms of value. It then reformats the information and places it in a special portion

```
3d:FIRST      :      1:      1:
```

Figure 4.3 Primitive List Form of the DESIGN CRITERIA.

of the primitive list. The possible alternatives were exercised and the corresponding correct output was generated, an example of which is contained in figure 4.3.

The ENVIRONMENT section, an example of which is contained in figure 4.4, contains the variable declarations for the input. It has 4 parts which are: procedure declarations, input signals, output signals, and duplex signals. While each of the above is optional, the controller will have to sense at least one input and emit one output to have some function. Each declaration can have its name, structure, precision, initial value, or the technology associated

```
ENVIRONMENT
  INPUT: RPM,8,TTL; FIRE SENSE,1,TTL;
        OIL PRES,8,TTL; END INPUT;
  OUTPUT: SD1,1,TTL; SD2,1,TTL;
        FIRE EXT,1,TTL; END OUTPUT;
  ARITHMETIC: STAG FLG,1; END ARITHMETIC;
```

Figure 4.4 ENVIRONMENT Section of the Input.

with it. The type of declaration decides which and how many of the attributes each variable will have. For the internal

program variables, in the ARITHMETIC section, the translator generates a system variable primitive and for each of the signals it produces the associated software primitive. Again, while the translator is parsing the structure of the input, the real work done is reformatting the names and their associated attributes into the appropriate primitive. No errors could be detected in exercising the program over this

```
4s.inputport {RPM,TTL:8)
5s.inputport {FIRE SENSE,TTL:1)
6s.inputport {OIL PRES,TTL:3)
7s.outputport {FIRE_EXT,TTL:1)
8s.var       {STAGFLG:1,0)
```

Figure 4.5 Primitive List Form of the Input.

portion of the input. An example of the output generated by the above example is contained in figure 4.5.

The PROCEDURES section contains the functions and tasks which establish the purpose of the controller being realized. The differences between functions and tasks are: functions are allowed only one basic statement and return a value while tasks allow multiple statements and perform a job. The key to both is the basic statement which is one of several types seen in most programming languages. The alternatives are: if-then, while-do, for loop, assignment, data input, data output, perform task, and wait. The only ones that might not be familiar are the "perform task" and "wait". "Perform task" allows for nested procedures and the "wait" statement causes the program to suspend itself for a prescribed period of time. An example of a task is contained in figure 4.6.

```

TASK OVRSPD;
  IF START SWIT THEN
    SENSE (RPM);
    SD5 := 0;
    IF RPM > 74 THEN SD5 := 1; END IF;
    ISSUE (SD5);
  END IF;
END OVRSPD;

```

Figure 4.6 PROCEDURES Section Input Example.

This section is where the parser really does its work. It must parse each statement in the procedure and generate an appropriate section of primitives, including temporaries, assembly-language-like software primitives and labels, which fulfill the intent of the statement. Each of the basic statements was exercised through the translator without any error detection, but because of the increased complexity of this section, 100% reliability cannot be confirmed. To do so would require a technique such as path testing. This requires that every logical path through a program be tested at least once. Another possibility is to construct test data which causes each branch in the program to be traversed [Ref. 15]. Algorithms for such testing exist, but the problems with each are the excessive time, CPU service, and output verification required. Therefore, complete path or branch testing was not attempted. However, the author's confidence in the correctness, after the testing that was conducted, is 100%. An output produced from the above input example is contained in figure 4.7.

The CONTINGENCY LIST section, an example of which is contained in figure 4.8, sets up the flow and timing for the controller by establishing how often each procedure should be executed. There are 4 types of statements allowed in this section: when-do, at time, simple do, and the every.

```

106t.generated for:OVRSPD
107s.proc      (OVRSPD:)

EVERY 1000MS DO CLOCK;
EVERY 100MS DO OVRSPD;

```

Figure 4.8 CONTINGENCY LIST Input Example.

determining what the format in the primitive list should be. For consistency, each was treated the same with blanks left in the columns in the "simple do", "every", and "at time" statements where a contingency name appears in the "when-do" statement. Examination of the example output in figure 4.9 and its comparison with the input example above will clarify this point. Alternative entries, such as the word "each", to replace the blanks are under consideration. The decision, based on the requirements of the functional mapper, will not occur prior to the submission of this thesis. Therefore, it is not possible to establish complete

A	1	:	RESET_SWIT	:	INIT	:	MS:	100,	0,	0,	0,	0

A	3	:		:	OVRSPD	:	MS:	100,	0,	0,	0,	0

Figure 4.9 Primitive List Form of the CONTINGENCY LIST.

correctness in this section. The program does act according to its given requirements but the possibility exists for these to change and, at that time, the section will have to be reverified.

Only the primitive list has been discussed above as program output. The translator also generates a symbol table and a scratch pad. Since the symbol table is unformatted, testing established only that the required information was present. The scratch pad is not a functional member of the CSDE and, therefore, was not tested. The error-checking routines within the translator were tested in so far as they were used in creating correct input file for the testing described above. This was considered adequate due to the impending completion of a syntax-directed editor for composing the CSDL input for the translator.

The input translator was built bottom-up in modular form. This methodology and the use of the automatically generated driver for the parsing routines were significant reasons for the relatively error-free results obtained during the testing of the translator as a whole.

V. CONCLUSIONS AND RECOMMENDATIONS

A. PROGRAM MAINTENANCE

The use of the automatic parser generator in providing the control tables for the translator allows the maximum degree of flexibility for program maintenance. The resulting main program is modular and space efficient, with anticipated changes, such as new emissions from the semantic routines, easily included in the system.

The most obvious portion of the system which will undergo modification is the CSDL grammar. Matelan states there is no capability in CSDL for notational extensibility, nor should there be [Ref. 16]. He points out it is doubtful that the average user can design extensions that will cause less harm than good and the provision of a good macro capability and extendable function/task libraries are preferred. This author disagrees. The advantage of using the parser generator is that a new set of tables can be produced for a modified CSDL with virtually no disturbance to the translator. The changes to the grammar must be consistent with the rules governing LL(1) grammars, but such modifications as the inclusion of new tokens or reserved words is within the capability of advanced program language students. In addition, to keep CSDL static, using the function/task libraries to realize new primitive operations as they become technologically feasible, only results in a less efficient controller. It could lead, in the worst case, to the inability to utilize the latest hardware technology available for controller design. This was most certainly not the intent.

One particular change to CSDL needs immediate attention. Many controllers require an analog input or output signal. Matelan, in his work, makes the assumption that analog information must be converted to a digital signal before it reaches the interface [Ref. 16]. If we have the ability to modify CSDL, this is no longer a complex issue. One possibility is to add a new input/output signal type with the CSDE calling for an A/D-D/A converter when this type is mapped to a library.

B. RECOMMENDATIONS FOR CSDE

The flow of information between modules in CSDE, prior to the impending completion of the designer and translator modules, is consistent. Since the system was implemented in Fortran and resides on one machine, there is no problem. But with the completion of the translator, the subject of this thesis, and the designer module having the same time schedule, the problem of interfaces becomes significant. The translator is written in Pascal and, while the output is a simple text file, the information flow will not be as it should. In addition, the designer module is being written in the "C" programming language which will generate, possibly, further interface problems. It is therefore recommended that the CSDE system be incorporated, as quickly as possible, into a data base management system such as Oracle. This was previously discussed in Chapter 3 of this thesis and the design of the data base was the subject of earlier research [Ref. 5]. This research pointed out that this redesign of CSDE should help streamline the operation and eliminate any complex programming schemes that were built out of necessity in earlier work. This concept will eliminate, completely, the interface problems, as the information will be input to and accessible from the database as

it passes from one module to the next. An overall improvement in system documentation, efficiency, and usability should result while, at the same time, allowing each module to maintain its individuality and function.

C. SUMMARY

In completing the design and implementation of the input translator, the objective of this thesis has been accomplished. The translator has been tested and fulfills the function required of the module in the Computer System Design Environment [Ref. 2]. The additional features added to the translator include an option to monitor the execution sequence in a variety of tracing modes and extensive error checking. While not considered integral parts of the program, these features were useful in its design and testing. As the CSDE evolves, these features might become superfluous, at which time they could be eliminated. But the information provided by the features should be considered prior to that decision.

The design methodology employed in the production of the translator was not innovative, but it allowed the program to be simple and straightforward. The use of the automatic parser generator was a time saver and proved to be a tool which will allow for the ease of future program maintenance as no other could. In one sense, we could say, while generating a module for a computer aided design system, a computer aided programming tool was central in the development.

The translator will reside in the CSDE on the VAX 11/780 VMS operating system. It is a Pascal program with the source and object code available under the filename "CSDL". The user instructions have been fully covered in the previous sections of this thesis.
